13. ABSTRACT (Maximum 200 words) This document presents detailed illustrated examples of facility optimization using HEC-1. The examples were designed to assist in data assembly and coding, output interpretation, and study management. Examples included were constructed in building block sequence to illustrate the relationships between the hydrologic, economic, and cost data to demonstrate selected capability. Examples illustrated include: (1) hydrologic model for existing conditions; (2) economic evaluation of existing conditions; (3) optimization of reservoir and pumping plant with no hydrologic constraints; (4) optimization of reservoir and pumping plant with hydrologic performance constraints; (5) optimization of reservoir, pumping plant, and diversion (unconstrained); (6) optimization of local projects, levee and channel modification (unconstrained); and, (7) optimization of reservoir, pumping plant, and local protection projects with uniform local protection level. The optimization algorithm (or search procedure discussed was developed to assist the planner in systematically and efficiently screening a large number of possible flood control alternatives. It should be emphasized that the optimization procedure of HEC-1 is a planning tool for determining potential and economically feasible flood control alternatives. Once those that have potential are selected, a more detailed simulation of the operational and hydraulic characteristics of a particular component will probably be required as various stages of study (leading to design) are undertaken.

INTRODUCTION

HEC-1 has been augmented to provide the capability of automatically determining the sizes of flood control system measures that result in maximizing total system net economic benefits subject to possible hydrologic performance targets. The system flood control measures that can be automatically sized are:

- . Detention storage reservoir(s)
- . Pumping plant(s)
- . Diversion(s)
- . Local protection(s), i.e., channel modification, levee, floodwall

This document presents detailed illustrated examples of facility optimization using HEC-1. The examples are designed to assist in data assembly and coding, output interpretation, and study management.

Examples included are constructed in building block sequence to illustrate the relationships between the hydrologic, economic and cost data and demonstrate selected capability. Examples illustrated include:

- Hydrologic Model for existing conditions.
- Economic evaluation of existing conditions.
- Optimization of Reservoir and Pumping Plant with no hydrologic constraints.
- Optimization of Reservoir and Pumping Plant with hydrologic performance constraints.
- Optimization of Reservoir, Pumping Plant and Diversion (unconstrained).
- Optimization of local protection projects; levee and channel modification (unconstrained).
- Optimization of Reservoir, Pumping Plant and local protection projects with uniform local protection level.

The basic reference for HEC-1 is the Users Manual listed as reference 1. The input data supplement, reference 2, updates Addendum 6 of reference 1 to include the facility optimization capability. Technical Paper No. 42, reference 3, describes the conceptual basis for the optimization problem and explains the characteristics of the flood control measures (except for the local protection capability that has recently been added) and a field application. Reference 4 summarizes various optimization algorithms and also includes a list of references pertinent to the subject matter presented herein. Reference 5 describes in detail the methodology involved in the calculation of expected annual damages.

BASIC EXAMPLE DESCRIPTION

The study area lies in the flood plain of a large river and is presently protected (to a degree) by a major levee. The levee greatly restricts outflow from the study area. Most of the storm runoff (within the study area) originates from the higher elevations (bluff areas), and most flooding occurs in the lower reaches of the study streams. Development in the flood hazard areas consists of agricultural crops, industrial-commercial areas and residential development. Figure 1 is a general map and schematization of the example area.

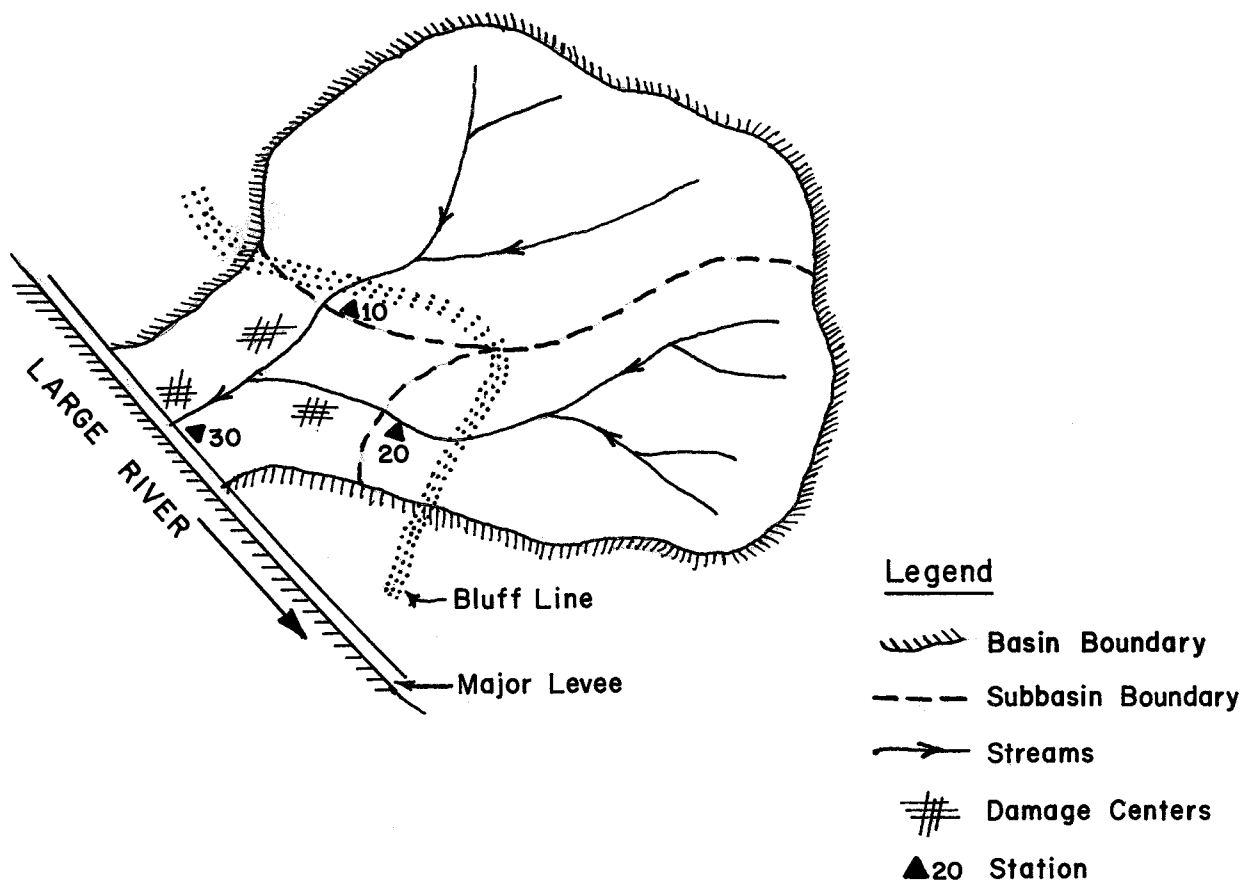

Proposals for protecting vulnerable areas from potential flooding include a detention storage reservoir at station 10, channel modification from station 10 to 30, levee from station 20 to 30, flow diversion (bypass) from station 20 to 30, and a pumping facility with forebay ponding at the basin outlet, station 30 (see Figure 1-a).

HYDROLOGIC MODEL

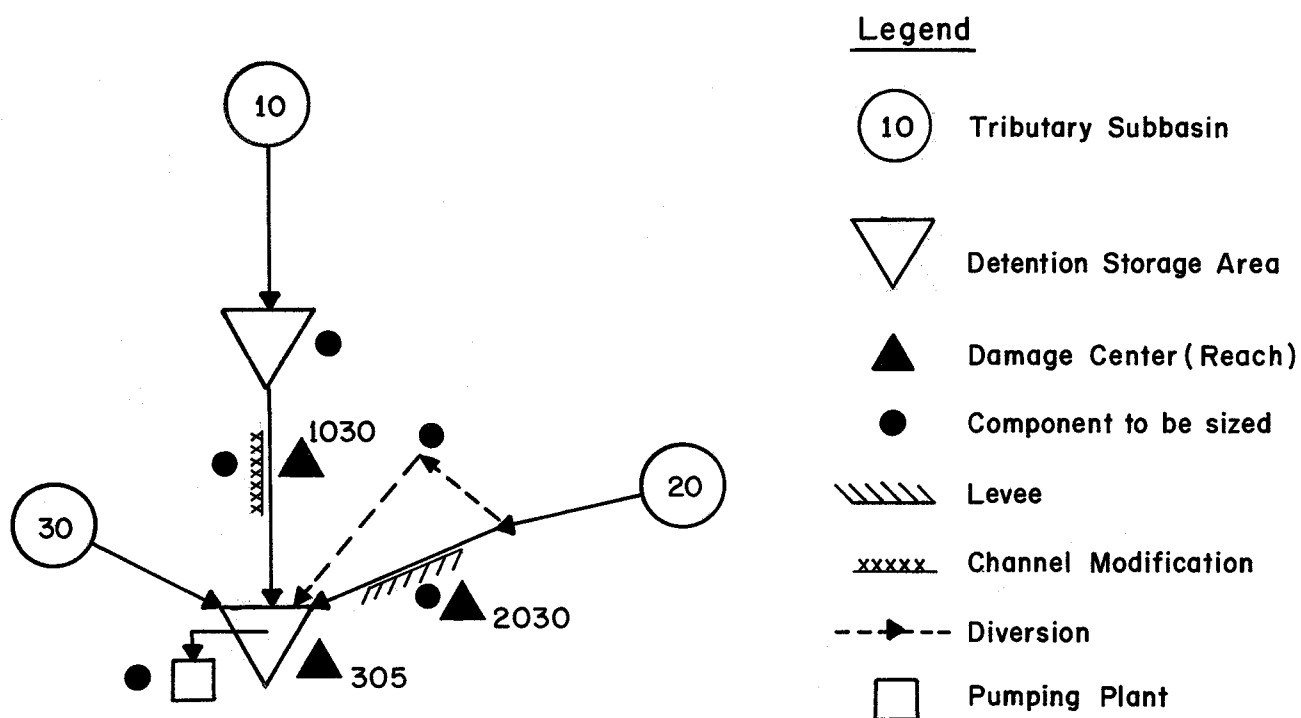

The hydrologic model for existing conditions is needed to define the base hydrology and provide a mechanism for evaluating the performance of proposed alternatives. Care must be taken in developing the base model to assure that all feasible alternatives can be easily evaluated and that the pattern hydrologic event is reasonably representative for the area, i.e., will not bias evaluation of alternatives. Data required for coding the basic hydrologic model is given in reference 1.

Since the primary objective of this supplement is illustration of flood control system component optimization, the hydrologic model has been kept simple in that discharge hydrographs of a specific event are read in rather than computed from rainfall-runoff relations during the optimization. (The hydrographs were essentially computed in a previous run). A hypothetical event was synthesized that ranged in frequency from the annual event (1.0 exceedence frequency) in the upper basin reaches to about the 5-year event (.2 exceedence frequency) in the lower basin. Channel routing criteria has been developed for the streams from multiple water surface profile calculations and for the restricted outlet at station 30 from the geometry of the outflow culvert and local topography. Table 1 (Appendix A) contains a tabulation of the hydrologic data for existing conditions.

Exhibit 1, page 1 of 2, is a listing of the HEC-1 input data for the hydrologic model. The hydrologic simulation of existing conditions indicates that for the selected event, the peak flows at stations 10, 20 and 30 are 5,370 cfs, 5,370 cfs and 10,154 cfs, respectively. The maximum storage level achieved at station 30 is 9,557 ac.ft. (maximum storage at station 30 not shown in computer printout included) and the peak outflow is 1,200 cfs.

Figure 1

ECONOMIC EVALUATION—EXISTING CONDITIONS

The economic evaluation for existing conditions provides the base from which economic benefits of alternatives may be evaluated. The economic evaluation of flood damages requires that flow-damage-frequency analysis be performed to develop "expected" (or average) annual damages. Reference 3 and Addendum 3 of reference 1 discuss the general application of flood damage frequency analysis to flood alternative evaluations and describe the concepts embodied in HEC-1.

The information required (in addition to the hydrologic model) is flow (or storage) - damage relationships and exceedence frequency relations at the damage centers. Additional coding is required to set up the multi-plan feature of HEC-1 and establish the range of floods needed to evaluate the hydrologic and economic effects of alternatives.

The damages in reaches 1030 and 2030 are mostly rural and result from overflow from the respective stream channels. Damage surveys have developed relationships between stage and damages for these reaches for a number of categories of damages. Water surface profile studies developed rating curves for the index stations as shown on Figure 1 so that flow-damage functions, as required by HEC-1, could be developed. The damages at location 305 are mostly urban, commercial and industrial (and are thus large) and occur because of ponding behind the levee. In HEC-1 storage is used instead of stage to represent level and thus a storage-damage function has been developed at this site. Storage is analogous to stage and the function is developed from the usual stage-damage relationship and a site stage-storage relationship.

The required exceedence frequency relationships for stations 10 and 20 were based on a partial duration series analysis because significant damages occur from events that occur more frequently than the annual event. These curves were developed from regional relationships developed in other studies. The required frequency relationship for station 30 is storage-exceedence frequency. This function was derived by developing synthetic events that would reproduce the regional curves at station 10 and 20, simulating the hydrologic operation of the system for these events, and plotting the resulting peak storage levels for these events versus their exceedence frequencies. Table 2 (Appendix A) contains the economic and frequency data for the damage centers.

The determination of the range of floods needed requires evaluation of the exceedence frequency relations, base hydrology and damage relations. The objective in developing the range of floods (multi-plan flood ratios) is to provide for automatic revision of the exceedence frequency relationship so that expected annual damages can be computed for alternative proposals. The procedure used for automatically revising the frequency curve is explained in Addendum 3 of reference 1. To accomplish this, the

ratios should develop floods that cover the range of damaging floods at all damage centers; in our example, the range extends from the six times per year event at damage centers 1030 and 2030 to above the .005 event at 305. The ratios contained in Table 2 (Appendix A) when applied to the synthetic event of the hydrologic model adequately cover the range.

The multi-plan coding has been prepared for two plans, which is necessary for the optimization examples following. The two plans are both for existing conditions which is of course redundant. If the multi-plan capability were being applied by itself, coding should be for as many alternatives as is desired for study. Exhibit 2, pages 1 and 2, are a complete listing of data input with notations as to revisions required from the basic hydrologic model and additions for the multi-plan evaluation.

The output for a multi-plan run includes complete hydrologic simulation for existing conditions and the proposed plan of improvement (none for example) for each of the range of runoff events (nine for the example) and integration of the damage relationships. The results indicate expected annual damages under existing conditions are \$33,580, \$33,580 and \$1,110,210 for damage reaches 1030, 2030 and 305, respectively.

The economic output (printout for station 1030 is page 3 of Exhibit 2) begins with a printout of control codes and includes (1) a listing of data input (ECONOMIC DATA FOR STATION 1030 PLAN 1) which includes exceedance frequency in events per year, peak flow and damages, (2) computation of expected annual damages (FLOOD DAMAGES FOR STATION 1030 PLAN 1) which includes allocation of probability intervals (PROB INT) to the range of flood events (FLOW) and incremental computed damage contribution to expected annual damages (SUM, TYPE 1, etc.) that are based on the product of PROB INT and damage associated with FLOW, and (3) the same information for the alternative plan. If the alternative plan had reduced annual damages, then the benefits (AVG ANN BFT) would be positive and equal to the difference between PLAN 1 and PLAN 2.

FLOOD CONTROL MEASURE OPTIMIZATION

The information required in addition to the hydrologic model and multi-plan economic data for flood control measure optimization are the performance parameters and cost relationships for the flood control features being considered. The mathematical structure for the optimization and the search strategy are discussed in detail in reference 3. It should be remembered (or understood) that economic optimum is achieved when the facilities are sized such that the computed difference between expected annual benefits and expected annual costs is maximized. The solution may proceed unconstrained or it can be constrained such that a minimum hydrologic performance at specified control points must be accomplished simultaneously with the net benefit maximization.

The general technique used is to successively operate the multi-plan simulation in a controlled fashion while automatically adjusting component sizes toward optimum.

SIZING RESERVOIR AND PUMPING PLANT — UNCONSTRAINED

The first optimization example will be the determination of the optimum (economic) sizes for a reservoir located at station 10 and a pumping plant to be located at station 30 that discharges through (or over) the levee. There is no minimum constraining hydrologic performance required. Information must therefore be assembled and coded that will describe, in a general way, the cost and performance of the storage reservoir and a pumping facility.

a. Detention Storage. — The detention storage reservoirs that may be considered with HEC-1 are those for which it is possible to define the operating characteristics as unique functions of the storage contents within the reservoirs. A reservoir with an uncontrolled outlet works exactly meets this requirement. To provide capability for automatic adjustment of operating characteristics (as is required for automatic optimization), a reservoir is characterized by (1) the outflow characteristics of a low level outlet, which is defined by the centerline elevation of the outlet and an orifice equation of the form:

$$Q = CA \sqrt{2g} (H)^{EXP} \dots \dots \dots (1)$$

where

- C = orifice discharge coefficient
- A = outlet area
- H = head on low level outlet
- g = acceleration of gravity
- EXP = exponent dependent on tailwater conditions, 0.5 if no tailwater

and (2) the overflow characteristics of a spillway which is defined by a weir equation of the form:

$$Q = C_* L H_*^{3/2} \dots \dots \dots (2)$$

where

- C* = weir discharge coefficient
- L = length of spillway
- H* = head on spillway

and (3) the site storage characteristics which are defined by an elevation-storage capacity relationship. For an index storage to be optimized, which is the storage at the elevation of the spillway crest, the above relationships are merged to define the reservoir's outflow as a function of the storage level in the reservoir (Modified Puls method of routing).

Two modes are possible for a reservoir optimization. In the usual mode (for our example) a reservoir that can be characterized by a low level outlet and an overflow weir as described above will be automatically adjusted in its index storage capacity, along with all other system components, to achieve the minimum value of the objective function (defined in reference 3). The alternative mode, not illustrated, permits optimization of the size of the low level outlet assuming the reservoir does not spill, which is appropriate for pondage in low lying areas.

The cost relationships for the reservoir in the usual mode consists of a capital cost function and an associated capital recovery factor for converting the capital cost to annual cost, and the annual cost of operation, maintenance and replacement expressed as a proportion of capital cost. The capital cost function includes land acquisition and construction costs, interest during construction, etc., expressed as a function of the index storage size of the reservoir. The capital cost for a specific reservoir size being evaluated during optimization is interpolated from this function and the equivalent annual cost is computed as the product of the capital cost and the capital recovery factor for the appropriate discount rate. The annual cost of operation, maintenance and replacement is the product of the annual cost proportion and the interpolated capital cost. The total annual cost of the reservoir is the sum of these two costs. Table 3 (Appendix A) contains the data describing the performance and cost of the proposed reservoir.

b. Pumping Plant — A pumping facility removes volume from the system at a rate equal to the pumping capacity. The performance characteristics of a pumping plant are defined by an initial threshold water level at which the pump is activated and the discharge capacity of the pumping facility. In this analysis, it is assumed that water pumped from the system does not later appear at other locations in the system. The cost of a pumping facility is computed from a capital cost function and an associated capital recovery factor for converting to equivalent annual cost, the annual operation, maintenance and replacement cost that is a proportion of the capital cost, and the annual power cost. The power cost is adjusted if the volume to be pumped changes as the system components sizes are being optimized. It can be demonstrated that no matter the pumping capacity, the power costs would not materially change if the volume to be pumped does not change. The annual power costs are therefore adjusted only for water that is removed from the system by diversions or other pumping facilities. The annual cost is the sum of the equivalent annual cost, annual operation and maintenance cost, and annual power cost. Table 4 (Appendix A) contains the data describing the performance and cost of the proposed pumping plant.

The coding requires initial estimates for the facility sizes (starting values) and a number of control codes to indicate location and type of facility to be sized. The starting values selected were 10,000 ac.ft. and 4,000 cfs for the reservoir and pumping plant, respectively. Exhibit 3, pages 1 and 2, are a listing of the input data for this example including notations of revisions and additions to the data required for the multi-plan evaluation example.

Exhibit 3, pages 3 - 43, are reproductions of the complete output from the optimization run. The output of an optimization run includes:

1. The derived optimum size for each facility in the system included in the optimization (page 43).
2. Complete hydrologic simulation of the system with and without the optimally sized facilities for the range of floods processed (nine for this example) (pages 6 - 42).
3. Economic expected annual damage analysis with and without the optimally sized facilities for each damage center in the system (pages 17, 24 and 41).
4. Costs for the derived system facilities (pages 11 and 40).
5. A summary of system cost, performance and net benefits (page 42).

The derived optimum sizes are 9,119 ac.ft. for the reservoir and 2,885 cfs for the pumping plant (summary page 43). The total capital cost is \$7,497,000 and system annual net benefits are \$173,000 (benefit cost ratio of 1.26). The derived values were adjusted from the starting values of 10,000 ac.ft. and 4,000 cfs which corresponded to a capital cost of \$8,740,000 and system net benefits of 158,000 (page 43). It is necessary, in each case, to test for possible local optima in the search procedure. This was accomplished by making a separate run with starting values of 3,000 ac.ft. and 500 cfs respectively. The derived sizes were 6,584 ac.ft. and 2,835 cfs costing \$6,591,000 and resulting in annual system net benefits of \$199,000. The results indicated that a local optimum did exist such that additional runs were made with different initial values until it could be reasonably concluded that the proper sizes were 6,584 ac.ft. for the reservoir and 2,835 cfs for the pumping plant.

The hydrologic performance can be characterized by the "degree of protection" provided, i.e., the exceedence frequency of the threshold of damaging flow. At damage center 1030, the zero damage exceedence frequency was reduced from about the 5 times per year event to about the annual event (deduced from page 17 and the additional runs made). Note that damages at station 1030 are quite small in relation to those at 305 and therefore probably had very little influence on the determination of the optimum sizes.

At damage center 305, the frequency of significant damages was reduced from about the 3-year exceedence interval event to about the 10-year event, which incidentally reduced expected annual damages by more than half.

Detailed study of the output can provide insight into the optimization methodology as well as the sensitivity of the system performance to a range of facility sizes. Pages 3 through 6 of Exhibit 3 contain detailed output on the progress of the optimization. The variables for optimization printed on page 3 are defined below and a review of the search procedure (reference 3) and the corresponding results from the output are described.

Variable Definition

NC = Counter denoting stage in search cycle (1-3)

M = Variable that is being adjusted for this cycle
(corresponds to fields on J2 card listed above
as SYSTEM OPTIMIZATION)

M1 = Next variable to be adjusted (optimized)

VAR(M) = Current value of variable M

VAR(M1) = Current value of variable M1

OBJ DEV = Used in connection with hydrologic performance constraint; described in example in next section

TANCST = Total annual cost of facilities at current values

ANDMG = Total annual damage for all damage centers for facilities at current values

O FTN(NC) = Objective function that is being minimized; in this example it is the sum of TANCST and ANDMG

Search Procedure (see reference 3)

- (1) First, trial sizes of all system components are nominated and the entire system is simulated in all of its hydrologic, costs, and economic detail to calculate the value of the objective function, which for unconstrained optimization is the sum of the equivalent annual cost (TANCST) and annual damage (ANDMG).

The first value (NC=1) of the objective function is 1018.883

- (2) Then the size of one component is decreased by a small selected amount (1 percent) and the simulation is repeated for the entire system to compute a new value of the objective function. This is repeated again resulting in three unique values of the objective function for small changes in the size of one component.

The values of the variable and objective function are

NC	VAR(M)	O FTN(NC)
1 $f(X_0)$	10000	1018.883
2 $f(X_0 - \Delta X)$	9900	1018.205
3 $f(X_0 - 2\Delta X)$	9800	1017.645

- (3) From these three values, an estimate is made of the component size that would result in the minimum value of the objective function. The computation of the adjustment is shown in Figure 2 and proceeds as follows:

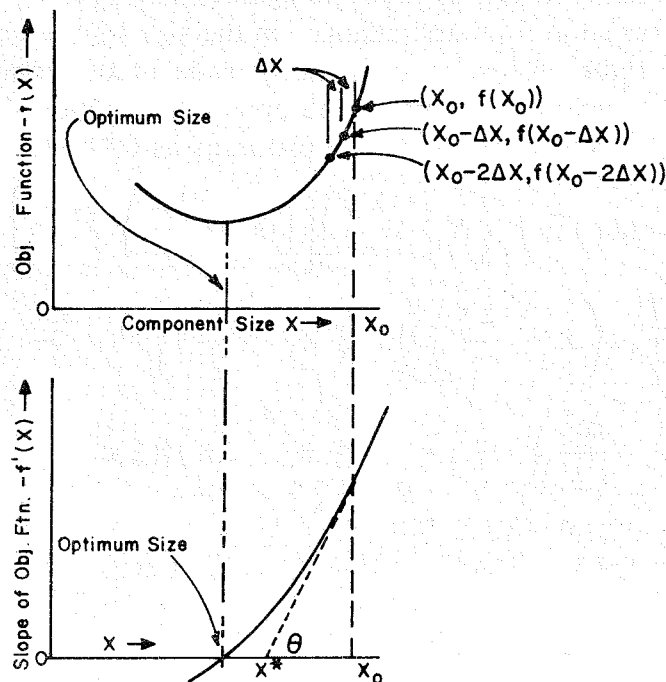

Figure 2.— Adjustment of Component Size by Newton-Raphson Convergence Procedure

$$f'' \left(X_o - \frac{\Delta X}{2} \right) = \tan \theta = f' \left(X_o - \frac{\Delta X}{2} \right) \left[\left(X_o - \frac{\Delta X}{2} \right) - X^* \right]^{-1} \dots \dots \dots (3)$$

$$\text{or } X^* = X_o - \left[f' \left(X_o - \frac{\Delta X}{2} \right) \right] \left[f'' \left(X_o - \frac{\Delta X}{2} \right) \right]^{-1} - \frac{\Delta X}{2} \dots \dots \dots (4)$$

$$\text{in which } f' \left(X_o - \frac{\Delta X}{2} \right) = [f(X_o) - f(X_o - \Delta X)](\Delta X)^{-1} \dots \dots \dots (5)$$

$$f'' \left(X_o - \frac{\Delta X}{2} \right) = [f(X_o - 2\Delta X) - 2f(X_o - \Delta X) + f(X_o)](\Delta X)^{-2} \dots \dots \dots (6)$$

and ΔX = incremental change in X ; X = size of variable being optimized;
 X_o = present size of component X ; and X^* = projected "new" size for X .
The calculation for adjustment of VAR(M) is as follows:

$$f' \left(X_o - \frac{\Delta X}{2} \right) = (1018.883 - 1018.205) / \Delta X = 0.678 / \Delta X \dots \dots \dots (7)$$

$$f'' \left(X_o - \frac{\Delta X}{2} \right) = [1017.645 - 2(1018.205) + 1018.883] / \Delta X^2 = .118 / \Delta X^2 \dots (8)$$

$$X_o = 10000; \Delta X = (.01) (10000) = 100$$

$$X^* = 10000 - \frac{0.678/100}{.118/(100)^2} - \frac{100}{2} = 9380. \text{ (to closest 10)} \dots (9)$$

- (4) After adjustment of the size of the system component, the entire system is simulated again in detail to compute the new value of the objective function and, provided the objective function has decreased, the procedure then moves to the second system component whose scale is to be optimized.

The output at this stage reads:

VAR 1 ADJ FROM 10000. to 9384.07

and one cycle for one variable has been completed.

- (5) The above procedure is repeated for the second and all subsequent components to be optimized.

Note that the same procedure is repeated for variable 9.

- (6) A single adjustment has now been made for each component for one complete search of the system component sizes. The procedure is then repeated for two more complete system searches.
- (7) The component whose change contributed the most to decreasing the objective function is adjusted next before another complete system search is performed.
- (8) The procedure is terminated when either no more improvement in the objective function can be made (within a tolerance) for the component making the greatest contribution to decreasing the objective function, or the complete search cycle is completed.

Note that occasionally no successful adjustment can be made. If the computed adjustment does not reduce the objective function, its value is successively reduced to the original value, testing for improvement at a number of steps (pages 5 and 6 of Exhibit 3).

The remaining output should be self-explanatory. Remember the output is for two plans (existing and the derived system) for nine flood events which results in 18 hydrologic simulations at each control point and two economic evaluations at all damage centers.

SIZING RESERVOIR AND PUMPING PLANT — HYDROLOGIC PERFORMANCE CONSTRAINED

The objective for this example is to determine the size of the facilities that will maximize the system net benefits while simultaneously meeting hydrologic performance targets expressed in terms of desired flow (storage) target and corresponding exceedence frequency. This example extends the previous example for the performance targets of

<u>Reach</u>	<u>Target Value</u>	<u>Exceedence Frequency (Events per Year)</u>
1030	1200 cfs	1.0
305	5000 ac.ft.	.05

The starting values were selected as 5000 ac.ft. and 5000 cfs, respectively.

Pages 1 and 2 of Exhibit 4 contain a listing of the input data with notations on coding revised and added. Pages 3 through 28 contain printout of selected pages of the output.

The derived optimum sizes are 7528 ac.ft. for the reservoir and 6044 cfs for the pumping plant (summary page 28). The total capital cost is \$9,889,000 and system annual net benefits are \$123,000 (benefit cost ratio

of 1.15). The derived values were adjusted from starting values of 5000 ac.ft. and 5000 cfs, respectively. The sensitivity of the solution to starting values was tested by making a separate run with starting values of 10,000 ac.ft. and 7000 cfs, respectively. The derived sizes were 6,007 ac.ft. and 6,570 cfs costing \$9,832,000 and resulting in annual net benefits of \$102,000. The hydrologic performance specified is achieved in that the degree of protection provided is 1.0 years (protection against the annual event) for reach 1030 and .05 (protection against the 20-year event) for reach 305 (see pages 15 and 26 of Exhibit 4).

The output detailing the progress of the optimization contains additional information related to the performance target constraints. The additional variables are (page 3, Exhibit 4):

Variable Definition

ISTA = Station where performance target specified

INT FLOW = Flow corresponding to the target exceedence frequency for the current values of the variables

TRG FLOW = Target flow for the target exceedence frequency

FLW OBJ = Component of penalty applied to objective function because of failure to meet target (illustrated later) for this station

FLW DEV = Difference between INT FLW and TRG FLW

OBJ DEV = Penalty applied to objective function because of failure to meet target (multiply)

The additional printout occurs for all stations where performance targets are specified (as many as desired). The optimization proceeds exactly as the previous (unconstrained) example except that the objective function is penalized whenever the performance targets are not met. Note that the first objective function is extremely large (.951E+06) because of the large penalty from not meeting the target for station 305 while the objective function when optimization is complete (page 10, Exhibit 4) essentially has no penalty (.106E+04). The computation of a value of the objective function for the condition blocked out on page 5 (Exhibit 4) will illustrate the role of the penalty assessment. See reference 3 for a description of the objective function.

$$FLW OBJ = [(FLW DEV) / (.10 TRG FLOW)]^4$$

Station 1030

$$FLW OBJ = \left(\frac{12.670}{120} \right)^4 = .0001$$

Station 305

$$\text{FLW OBJ} = \left(\frac{782.138}{500} \right)^4 = 5.988$$

Objective Function Assessment

$$\text{OBJ DEV} = .0001 + 5.988 = 5.988$$

$$0 \text{ FTN}(\text{NC}) = (\text{TANCST} + \text{ANDMG}) (\text{OBJ DEV} + 1)$$

$$0 \text{ FTN}(\text{NC}) = (774.217 + 265.434) (5.988 + 1) = \underline{\underline{7264.80}}$$

The printout at the bottom of the pages on which economic output is shown (page 15 for example) summarizes the performance target and final regulated values.

SIZING RESERVOIR, PUMPING PLANT AND DIVERSION

A proposal offered at past public meetings has been to divert a portion of the runoff from subbasin 20 at station 20 into the adjacent watershed (which is presently undeveloped) both to reduce flooding in the downstream reaches and increase wetlands in the adjacent watershed to improve wildlife habitat. This example extends the previous reservoir and pumping plant example (unconstrained) to include a diversion from station 20.

A diversion transfers flow between locations within the system. The performance characteristics are defined by a threshold flow and a diversion capacity. The concept of the diversion relationship is indicated in figure 3. Water diverted may be returned to the system at any downstream location so that it is possible to characterize facilities which would bypass a portion of flood flows around a damage center. Flow may also be permanently diverted from the system, which will be done for this example. The cost is characterized similar to a pumping plant by a capital cost function, a capital recovery factor and annual operation, maintenance and replacement factor.

Table 5 (Appendix A) summarizes the performance and cost data for the proposed diversion.

The coding to include a diversion at station 20 is noted on the listing of input data, pages 1 and 2 of Exhibit 5. Note that it was necessary to include a dummy reservoir at station 20 in order to accommodate the requirements for a diversion.

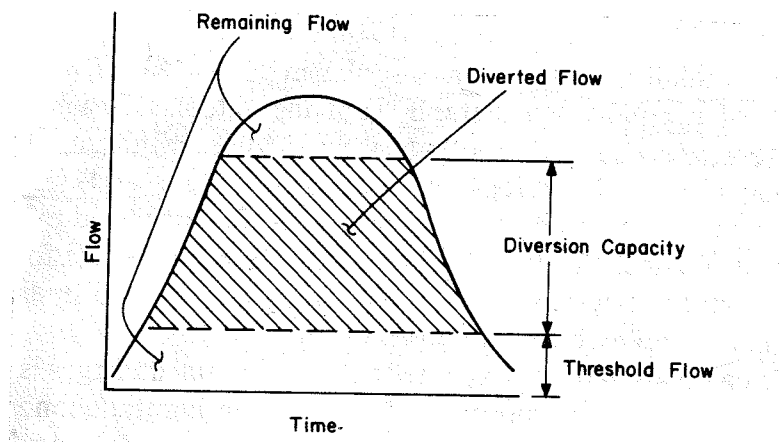

Figure 3. — Effect of Diversion on Flood Hydrograph

Pages 3 through 34 of Exhibit 5 contain selected pages of the output. The derived optimum sizes are 6620 ac.ft. (index storage) for the reservoir, 863 cfs for the diversion and 2250 cfs for the pumping plant (summary page 34). The total capital cost is \$7,099,000 and system net benefits are \$197,000 (benefit cost ratio of 1.33). The derived values were adjusted from starting values of 4000 ac.ft., 500 cfs and 1000 cfs, respectively, for the reservoir, diversion, and pumping plant. The sensitivity of the solution to starting values was tested by making a separate run with new starting values of 10,000 ac.ft., 3000 cfs and 4000 cfs, respectively. The derived sizes were 6648 ac.ft., 1393 cfs and 2160 cfs, respectively, costing \$7,617,000 and resulting in annual net benefits of \$167,000. In comparison with the previously derived values, it appears the diversion should be the smaller size. Additional runs demonstrate the value of testing a few starting values in an effort to locate a reasonable optimum.

The hydrologic performance of the derived system can be characterized by the degree of protection provided, i.e., the exceedence frequency of the threshold of damaging flows. At control point 1030, the 0 damage exceedence frequency was reduced from about the five times per year event to about the annual event (about the same as the example without the diversion). At control point 2030, the 0 damage exceedence frequency was not materially changed from the five times per year event. At control point 305, the frequency of significant damage was reduced from about the 3-year exceedence interval event to between the 10 and 15-year events. The residual damages for the system are reduced to about 1/3 of the damages under existing conditions.

SIZING LOCAL PROTECTION PROJECTS

Local protection projects include levees, floodwalls and channel modifications. Ignoring for the moment natural valley storage effects, the hydrologic and economic effects of local projects are truly local,

i.e., do not interact with the system hydrology. If this is the case, and it will be unless the modification is extensive, then a local project can be completely characterized performance-wise by a design Q (or storage) and a flow (or storage) damage function. Damages are usually negligible below the design flow and follow a curve related to the local site hydraulics and damage potential above this point. A levee or floodwall essentially truncates the damage function below the design flow (basic hydraulic-economic relationship unchanged) while channel modifications lower the relationship in response to the improved conveyance characteristics.

The concept embodied in HEC-1 is that a design flow is associated with a unique damage relationship and therefore if the range of feasible design flows are known, the relationship for a specific design flow within the feasible range could be determined. The relationship (flow or storage-damage) for a specific design flow is determined by interpolating between the relationships defining the feasible range. The relationships defining the feasible range are termed "pattern functions;" the minimum design damage function corresponding to the design flow considered the lowest value feasible and the maximum design damage function corresponding to the design flow considered the highest value feasible.

The local projects considered for this example are a channel modification for reach 1030 and a levee for reach 2030. The pattern damage functions for reach 1030 were developed from water surface profile and economic studies. The minimum design damage function corresponds to a "clear and snag" alternative and was constructed by computing water surface profiles for a smoothed boundary to develop a rating curve at the index station that was subsequently combined with an area, elevation, damage relationship. The design flow associated with this function is 1700 cfs, the lower limit of design flow. The maximum design function corresponds to a 40 ft. bottom width, 2 to 1 side slope channel enlargement and was constructed by computing water surface profiles for modified hydraulic geometry to develop a rating curve that was subsequently combined with an area, elevation, damage relationship. The design flow associated with this function is 8300 cfs, the upper limit of design flow for the enlarged channel. Table 6 (Appendix A) summarizes the performance and cost data for the proposed channel modification for reach 1030. Table 6 also contains a generated damage function for a specific design flow to illustrate the interpolation concept.

The upper and lower pattern damage functions for reach 2030 are the same and correspond to existing conditions. The reason for the correspondence is that the effect of a levee is primarily to truncate the function at the design flow. Some change is possible for various designs if the flow area is greatly restricted by the levees. The example assumes no significant conveyance change from the levees, though the methodology does not require the assumption. Table 7 (Appendix A) summarizes the cost and performance data for the proposed levee reach.

The existing conditions damage relationships, cost and runoff hydrology for reaches 1030 and 2030 have been purposefully made the same so that

the methodology developed for handling local projects can be easily observed. The example contains only local projects (other damage centers and alternatives removed) so that the difference in the derived sizes of the two alternatives should only be due to differences in their performance, i.e., modified damage relationships. A listing of the input data for this example is contained on pages 1 and 2 of Exhibit 6.

Pages 3 through 15 of Exhibit 6 contain selected pages of the output of the optimization run.

The derived optimum sizes are about 5000 cfs design flow for both the channel modification reach and the levee reach. This amounts to about a 0.7 exceedence frequency degree of protection. The total capital cost is \$207,000 and system annual net benefits of \$30,000. The derived values were adjusted from starting values of 2000 cfs design flow for each facility. It is interesting to note that while both facilities began and ended with the same values, the adjustment route to the optimum was different. There was no requirement that they both end up the same size (see pages 3 through 5 of Exhibit 6). In addition, note that while the values derived were the same, the net benefits were different because the damage relationships were quite different. The channel modification cost \$104,000 and had average annual benefits of 27,000 for annual net benefits of \$19,000 (benefit cost ratio of approximately 3.4). The levee cost \$103,000 and had average annual benefits of \$19,000 for annual net benefits of \$11,000 (benefit cost ratio of approximately 2.4).

-sizing reservoir, pumping plant, diversion, and uniform protection local projects

This final example includes all the proposed components that have been previously illustrated. The optimization will be unconstrained and the uniform protection level option for the local projects will be used. The uniform protection level option will in effect cause a "degree of protection" to be optimized for the two local protection projects. A complete listing of the input data is contained on pages 1 through 3 of Exhibit 7 and the complete output on pages 4 through 39.

The derived optimum sizes are 6701 ac.ft. for the reservoir, 0.2 exceedence frequency for the levee and channel projects (2947 cfs for the channel modification and 7660 cfs for the levee), 670 cfs for the diversion and 2450 cfs for the pumping plant for a total capital cost of \$7,408,000 and system net benefits of \$196,000 (benefit cost ratio of 1.31). The optimum sizes were adjusted from starting values of 4000 ac.ft. for the reservoir, 0.2 exceedence frequency (uniform protection) for local projects, 500 cfs for the diversion and 1000 cfs for the pumping plant. A comparison of Exhibits 5 and 7 indicates that the inclusion of local projects has very little effect on the optimum sizes of the major facilities (reservoir and pumping plant). The diversion capacity was lowered slightly from that derived in Exhibit 5 which probably means that it is more efficient to protect reach 2030 by the levee project.

OBJECTIVE OF THE FLOOD CONTROL SYSTEM COMPONENT OPTIMIZATION UTILIZING HEC-1

The optimization algorithm (or search procedure) discussed in this training document has been developed to assist the planner in systematically and efficiently screening a large number of possible flood control alternatives. Although there is an upper limit to the number which can be satisfactorily and economically optimized in one particular computer run, it is still possible to analyze a large number of components by grouping. In the Phoenix Urban Study, Los Angeles District Corps of Engineers (reference 6), there were eight upstream storage alternatives to be evaluated. Although each component was analyzed individually, it was possible to determine which component and combination of components were economically feasible by making several runs in groups of two and three components and comparing the economic and hydrologic consequences.

It should be emphasized that the optimization procedure of HEC-1 is a planning tool for determining potential and economically feasible flood control alternatives. Once those that have potential are selected, then a more detailed simulation of the operational and hydraulic characteristics of a particular component will probably be required as various stages of study (leading to design) are undertaken.
